## A Search for the Neutrinoless Double Beta Decay of Xenon-136 with Improved Sensitivity from Denoising

Clayton G. Davis

April 3, 2014

### Outline

 $\beta\beta 2\nu$  and  $\beta\beta 0\nu$  Decay

The EXO-200 Detector

Denoising

Results

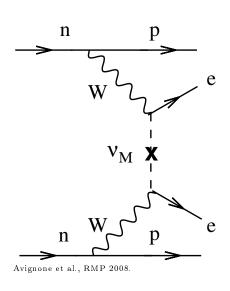

### What is Double-Beta Decay?

Feynman diagram for  $\beta\beta 2\nu$  decay. Equivalent to two single- $\beta$  decays:

$$2n \to 2p + 2e^{-} + 2\bar{\nu}_{e}$$
  
eg.  $^{136}Xe \to ^{136}Ba + 2e^{-} + 2\bar{\nu}_{e}$ 

### What is Double-Beta Decay?

Feynman diagram for  $\beta\beta 2\nu$  decay. Equivalent to two single- $\beta$  decays:

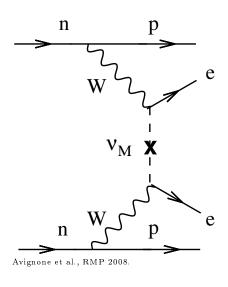

$$2n \to 2p + 2e^{-} + 2\bar{\nu}_{e}$$
  
eg.  $^{136}Xe \to ^{136}Ba + 2e^{-} + 2\bar{\nu}_{e}$ 

Feynman diagram for  $\beta\beta 0\nu$  decay. Neutrinos annihilate each other:

$$2n \rightarrow 2p + 2e^{-}$$
  
eg.  $^{136}Xe \rightarrow ^{136}Ba + 2e^{-}$ 

 $\beta\beta 2\nu$  is allowed in the Standard Model;  $\beta\beta 0\nu$  is not.

### Implications of Double-Beta Decay

► Lepton number changes:

$$\Delta L = +2$$

Neutrinos can convert to their own antiparticle:

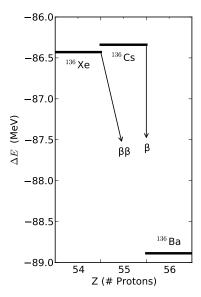

$$\bar{\nu}_{\mathrm{R}} \rightarrow \nu_{\mathrm{L}}$$

➤ Neutrinos have mass through a Majorana interaction:

$$-\frac{m_L}{2}\left(\overline{\Psi_L^c}\Psi_L+\overline{\Psi_L}\Psi_L^c\right)$$

$$-rac{\mathrm{m_R}}{2}\left(\overline{\Psi_{\mathrm{R}}^{\mathrm{c}}}\Psi_{\mathrm{R}}+\overline{\Psi_{\mathrm{R}}}\Psi_{\mathrm{R}}^{\mathrm{c}}
ight)$$

### The A = 136 Isobar

 $^{136}$ Cs undergoes single- $\boldsymbol{\beta}$  decay.

 $^{136}$ Xe cannot, due to energy conservation – but it can  $\beta\beta$  decay through  $^{136}$ Cs to  $^{136}$ Ba.

The Q-value of  $^{136}$  Xe  $\rightarrow$   $^{136}$  Ba is  $2457.83 \pm 0.37$  keV, shared between all final products of the decay.

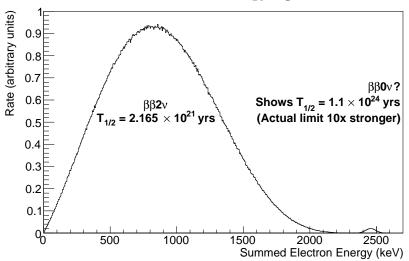

We observe energy in electrons; energy in neutrinos is lost.

## Ideal Double-Beta Energy Spectrum

 $^{136}\mathrm{Xe}~\beta\beta2\nu$  produces a smooth energy spectrum; "missing" energy carried off by neutrinos.

### Ideal Double-Beta Energy Spectrum

 $^{136}$ Xe  $\beta\beta0\nu$  has no neutrinos, so no "missing" energy; monoenergetic peak at Q = 2458 keV.

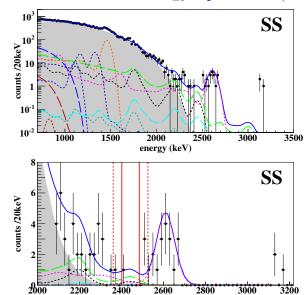

## Ideal Double-Beta Energy Spectrum

If the  $\beta\beta 0\nu$  peak exists, neutrinos have Majorana mass; peak height gives a measurement of that mass:

$$\left[T_{1/2}^{0\nu}\right]^{-1} = G_{0\nu}(Q_{\beta\beta}, Z) |M_{0\nu}|^2 \langle m_{\beta\beta} \rangle^2.$$

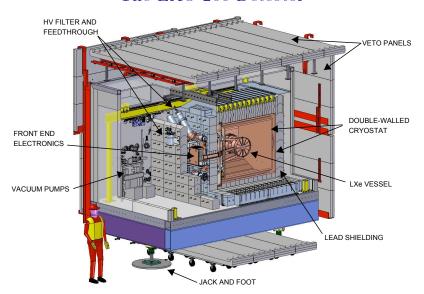

## Observed Energy Spectrum (May 2012)

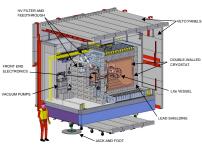

energy (keV)

32.5 kg-yrs (vs. 99.8 kg-yrs for the present analysis)

### The EXO-200 Detector

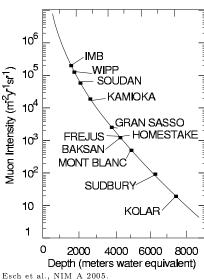

### The EXO-200 Detector

To search for rare decays, low background is key:

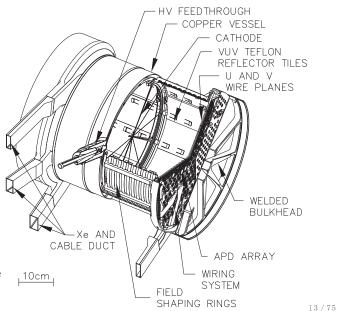

- Clean (low-radioactivity) materials surrounding TPC.
- ▶ Deep underground to avoid cosmogenics.

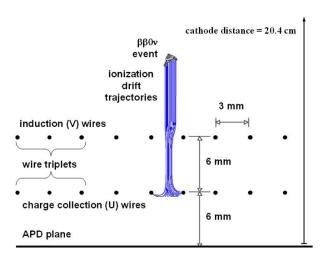

### EXO-200 TPC

110 kg of liquid xenon in active volume, enriched to 80.6% in <sup>136</sup>Xe, contained in a time projection chamber (TPC).

Xenon continuously circulates through purifiers outside of the cryostat.

### EXO-200 TPC

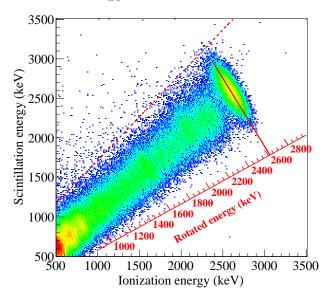

Charge drifts under an electric field and is collected by wires on the anodes. Light is observed by APDs behind the wires.

### EXO-200 TPC

Charge drifts under an electric field and is collected by wires on the anodes. Light is observed by APDs behind the wires.

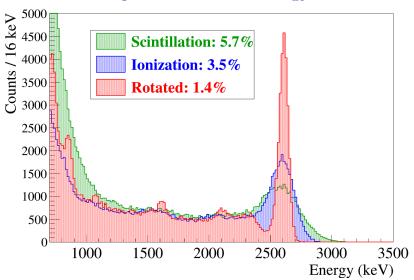

## Energy from Ionization and Scintillation

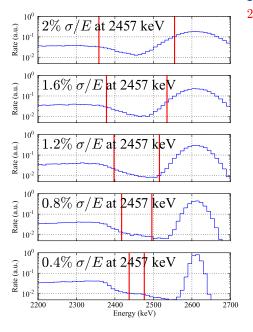

Energy is independently measured from scintillation and ionization.

They are anticorrelated – better energy resolution from both together than either independently.

## Impact of Rotated Energy

### Simulation

## Primary Backgrounds:

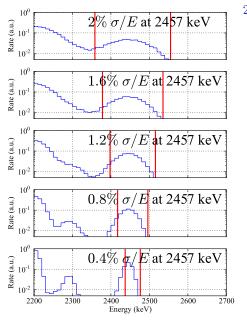

Th,  $^{238}$ U, and  $^{137}$ Xe Energy resolution is measured as  $\sigma$ /mean of a peak at the Q-value. Typically 1.5-2% for us.

Impact of background goes like integral of pdf between red  $2\sigma$  lines.

<sup>232</sup>Th gamma line at 2615 keV, so energy resolution has strong impact down to about 1.2%.

Beyond that, impact on <sup>232</sup>Th is much less.

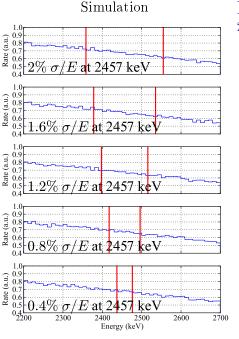

### Simulation

## Primary Backgrounds:

Th, <sup>238</sup>U, and <sup>137</sup>Xe <sup>238</sup>U has a 2448-keV gamma line, indistinguishable from 2457-keV Q-value except with extremely good resolution.

So, even down to 0.4% energy resolution, most of the <sup>238</sup>U peak at 2448 keV is still within our energy window. Impact of resolution on <sup>238</sup>U backgrounds is small.

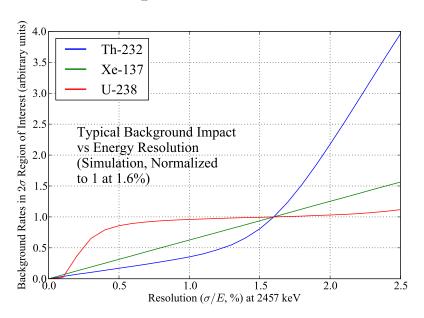

# Primary Backgrounds: <sup>232</sup>Th, <sup>238</sup>U, and <sup>137</sup>Xe

 $^{137}$ Xe is a cosmogenic background from  $^{136}$ Xe which  $\beta$ -decays; endpoint of 4173 keV.

<sup>137</sup>Xe spectrum is smooth around Q-value, so background impact goes linearly with resolution.

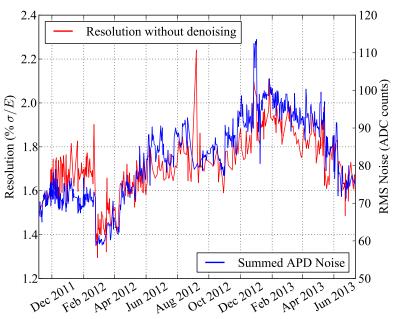

### Backgrounds vs. Resolution

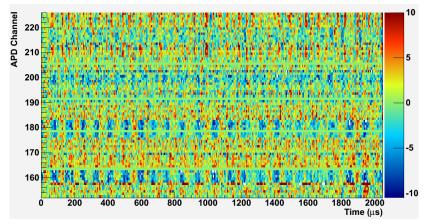

### Time Variation of Resolution

### Time Variation of Resolution

### APD Noise is Correlated across Channels

Correlated noise ⇒ offline denoising of some sort should work!

Three types of noise in the scintillation measurements:

- ► Electronic noise.
- ▶ Photon fluctuations.
- ► Gain fluctuations.

A "denoising" algorithm should minimize all three.

Three types of noise in the scintillation measurements:

► Electronic noise.

← Additive; use fewer channels.

- ▶ Photon fluctuations.
- ► Gain fluctuations.

A "denoising" algorithm should minimize all three.

Three types of noise in the scintillation measurements:

► Electronic noise.

← Additive; use fewer channels.

▶ Photon fluctuations.

← Poissonian; use more channels.

► Gain fluctuations.

← Poissonian; use more channels.

A "denoising" algorithm should minimize all three.

Three types of noise in the scintillation measurements:

► Electronic noise.

- ← Additive; use fewer channels.
- ▶ Photon fluctuations.
- ← Poissonian; use more channels.

► Gain fluctuations.

← Poissonian; use more channels.

A "denoising" algorithm should minimize all three.

Most denoising algorithms transform an input waveform to an output waveform, with pulses amplified and additive noise reduced.

Here we're trying to reduce the impact of noise which is correlated with pulses. That means traditional denoising won't accomplish what we need.

So, "denoising" for us means producing a noise-tolerant estimate of the scintillation energy.

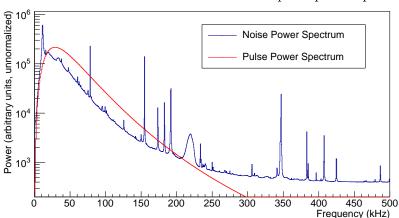

There are also three approaches to reducing the impact of noise:

- ► Frequency weighting.
- ► Channel weighting.
- ► Exploit noise correlations.

There are also three approaches to reducing the impact of noise:

- ► Frequency weighting.
- ► Channel weighting.
- ► Exploit noise correlations.

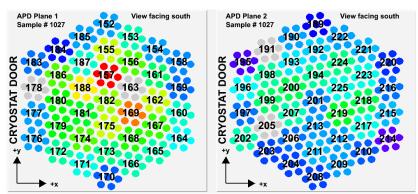

Noise and pulse power spectra.

There are also three approaches to reducing the impact of noise:

- ► Frequency weighting.
- Channel weighting.
- Exploit noise correlations.

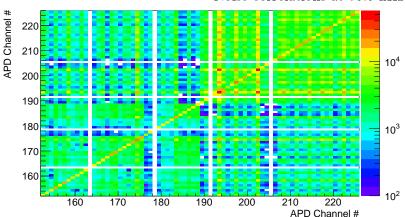

APD pulse magnitudes.

There are also three approaches to reducing the impact of noise:

- ► Frequency weighting.
- ► Channel weighting.
- ► Exploit noise correlations.

Noise correlations at 78.6 kHz.

### Waveform Model

When there is one energy deposit in the xenon, the APD waveform  $X_i[f]$  (in frequency space) on channel i can be modeled:

$$X_i[f] = M_iY_i[f] + N_i[f]$$
, where:

- ► Y<sub>i</sub>[f] is the unit-magnitude template pulse for channel i.
- M<sub>i</sub> is the magnitude of the pulse observed on channel i, including the scintillation energy and Poisson fluctuations in photon statistics and gain.
- $ightharpoonup N_i[f]$  is the additive (electronic) noise on channel i.

To complete our model, we need to understand the distributions of the random variables:

- ► How M<sub>i</sub> depends on the unknown energy E.
- ► How magnitudes M<sub>i</sub> and M<sub>j</sub> are correlated.
- ▶ How electronic noise  $N_i[f]$  and  $N_j[f]$  are correlated.

### Electronic Noise

To measure the electronic (additive) noise, we need waveforms with no pulse.

Fortunately, EXO-200 is a low-background detector: most of the time all it measures is noise.

So, this is fairly easy: use our noise data to measure all of the pairwise noise correlations.

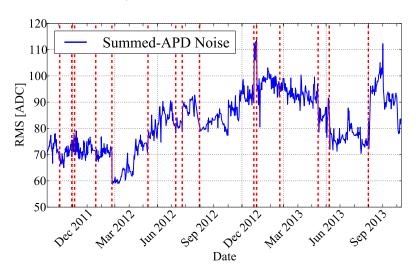

Explicitly, we measure:

$$\Big\langle N_i^R[f]N_j^R[f] \Big\rangle, \, \Big\langle N_i^R[f]N_j^I[f] \Big\rangle, \, \mathrm{and} \, \, \Big\langle N_i^I[f]N_j^I[f] \Big\rangle,$$

where  $N_i^R[f]$  and  $N_i^I[f]$  are the real and imaginary parts of  $N_i[f]$ .

### Electronic Noise

Main detail: the electronic noise changes over time (mostly in discontinuous steps).

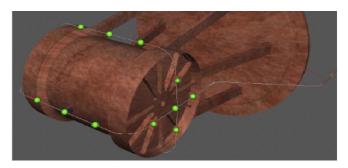

## Lightmaps

The expected pulse height  $M_i$  on a channel i from a deposit at position  $\vec{x}$  and time t is described by a lightmap  $L_i(\vec{x}, t)$ :

$$\langle M_i \rangle = L_i(\vec{x}, t)E$$
.

To measure  $L_i(\vec{x}, t)$ , we need a known-energy deposit for all position and time bins. But we don't have that much data: calibration sources give us good statistics, but aren't near every position.

## Lightmaps

The expected pulse height  $M_i$  on a channel i from a deposit at position  $\vec{x}$  and time t is described by a lightmap  $L_i(\vec{x}, t)$ :

$$\langle M_i \rangle = L_i(\vec{x}, t) E.$$

To reduce the amount of statistics needed, we make an approximation that  $L_i(\vec{x}, t)$  is separable into spatial and temporal components:

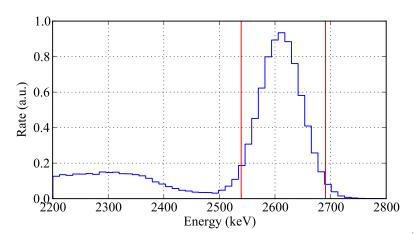

$$L_i(\vec{x}, t) = R_i(\vec{x})S_i(t)$$
.

So, rather than needing one known-energy deposit per position per time, we need one per position during the whole history of EXO-200.

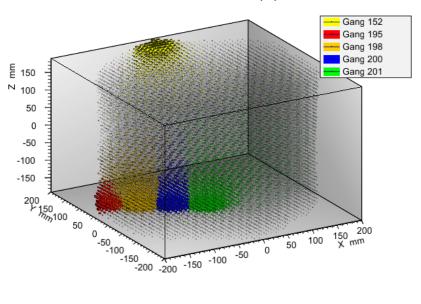

(We do this assuming that APD gain varies over time, but light collection does not, and gain does not depend on the position of the deposit.)

## Lightmaps

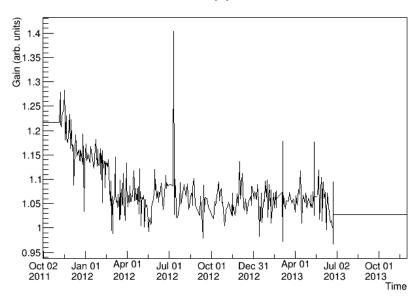

With this simpler form for the lightmap, we can measure  $R_i(\vec{x})$  and  $S_i(t)$  by combining all thorium source calibration events from the <sup>208</sup>Tl 2615-keV gamma line. It is a clean, well-isolated peak:

## Lightmaps: $R_i(\vec{x})$

## Lightmaps: $S_i(t)$ for i = 152

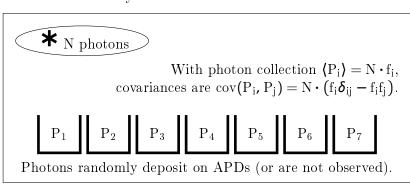

## Light Collection Noise

The expected pulse height  $M_i$  on a channel i from a deposit at position  $\vec{x}$  and time t is described by a lightmap  $L_i(\vec{x}, t)$ :

$$\langle M_i \rangle = L_i(\vec{x}, t)E.$$

What about covariances of M<sub>i</sub>?

Photon collection by the APDs has a multinomial distribution:

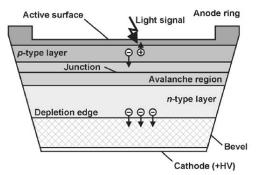

## Light Collection Noise

The expected pulse height  $M_i$  on a channel i from a deposit at position  $\vec{x}$  and time t is described by a lightmap  $L_i(\vec{x}, t)$ :

$$\langle M_i \rangle = L_i(\vec{x}, t) E.$$

What about covariances of M<sub>i</sub>?

We treat an APD as having two operational phases:

- Active surface: photons are converted to photoelectrons (with a quantum efficiency).
- Avalanche region: photoelectrons are amplified by avalanche (APD gain).

Both processes produce Poissonian fluctuations. $_{42/75}$ 

## Denoising: An Optimization Problem

So, the waveforms  $X_i[f]$  are modeled by:

$$X_i[f] = M_i Y_i[f] + N_i[f],$$

and we have full descriptions of the random variables  $\mathrm{M}_{\mathrm{i}}$  and  $\mathrm{N}_{\mathrm{i}}[\mathrm{f}].$ 

Linear real-valued energy estimators  $\widehat{E}$  take the form:

$$\widehat{E} = \sum_{if} A_i[f] X_i^R[f] + B_i[f] X_i^I[f],$$

where  $A_i[f]$  and  $B_i[f]$  are parameters we can adjust.

Problem: minimize the mean square error,  $\langle (E - \widehat{E})^2 \rangle$ .

Constraint: estimator is unbiased,  $\langle E - \widehat{E} \rangle = 0$ .

## Denoising: An Optimization Problem

The solution is a big matrix equation which we write in a compact way:

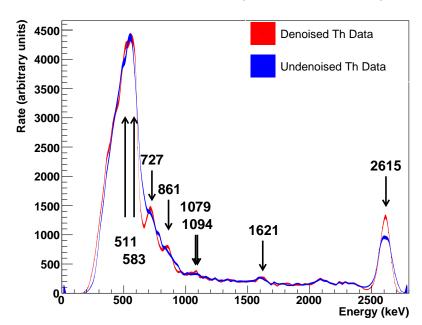

$$\begin{pmatrix} \mathbf{N} + \mathbf{P} & \mathbf{C}^\mathsf{T} \\ \mathbf{C} & 0 \end{pmatrix} \begin{pmatrix} \mathbf{A} \\ \boldsymbol{\lambda} \end{pmatrix} = \begin{pmatrix} 0 \\ 1 \end{pmatrix}.$$

The LHS matrix is a  $143,291 \times 143,291$  sparse matrix with roughly twenty million non-zero entries.

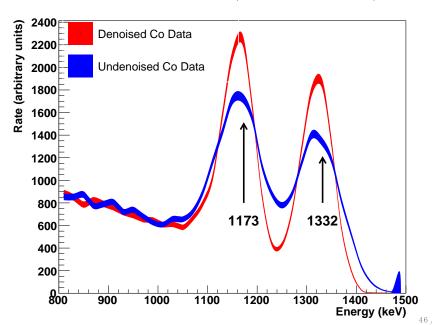

We need to solve this system once for each event, and there are hundreds of millions of events. Fortunately this is an embarassingly parallel problem, so we can just find a big computing system and do it.

NERSC, at LBNL, was used for this analysis; we required roughly 50,000 core-hours to do this processing.

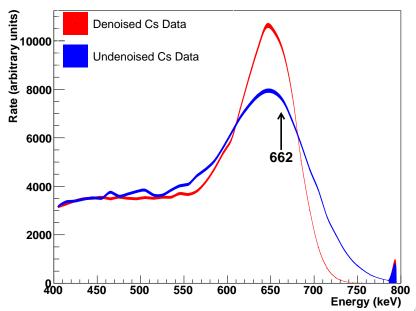

# <sup>228</sup>Th Source Spectrum (Before and After)

# <sup>137</sup>Cs Source Spectrum (Before and After)

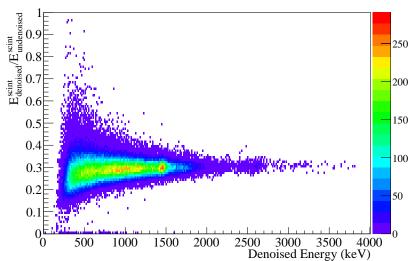

## Energy Resolution (Before and After)

## Energy Resolution (Before and After)

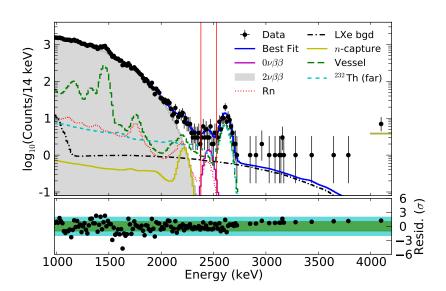

## Relative Change in E<sup>scint</sup> vs. Energy

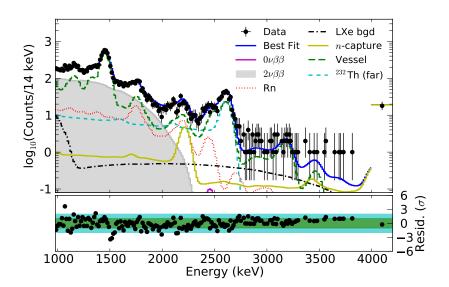

Lower-energy events tend to move more, as expected; very few outliers. A few events cannot be denoised by the current code; these give a ratio of zero.

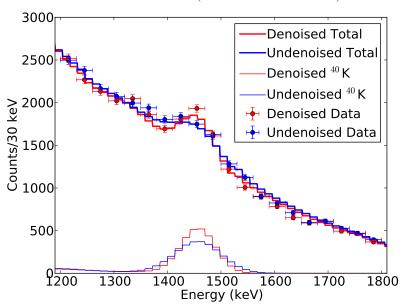

## Best Fit (Denoised)

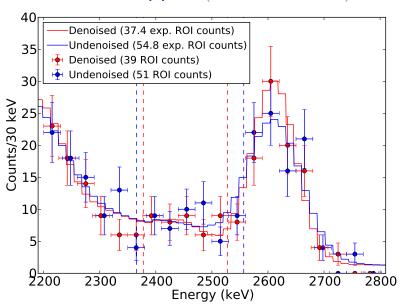

## Best Fit (Denoised), multi-site backgrounds

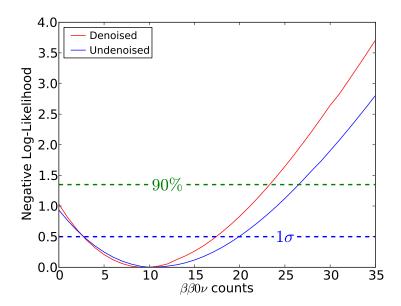

## Fits around <sup>40</sup>K (Before and After)

## Fits around $\beta\beta 0\nu$ (Before and After)

## $\beta\beta$ 0 $\nu$ Profile Likelihood (Before and After)

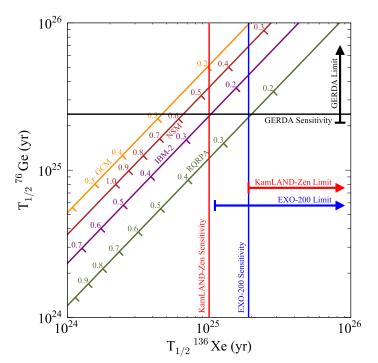

#### Results

#### At 90% confidence:

- ▶ Fewer than  $24 \beta \beta 0 \nu$  counts vs 27 without denoising.
- ►  $T_{1/2}^{0\nu} > 1.1 \cdot 10^{25}$  years vs  $9.8 \cdot 10^{24}$  without denoising.
- ►  $\langle m_{\beta\beta} \rangle$  < 190 450 meV vs 200 480 without denoising.

ROI background is reduced by 32%, corresponding to an even better improvement in average sensitivity: 17% in  $T_{1/2}$  and 9% in  $\langle m_{\beta\beta} \rangle$  (depending on exact mix of backgrounds).

# Thank You!

Questions?

## Backup Slides

## Anticorrelated Scintillation/Charge

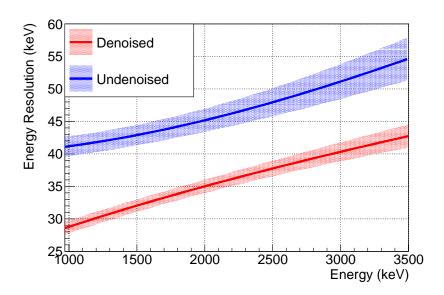

## Why not the Anscombe transformation?

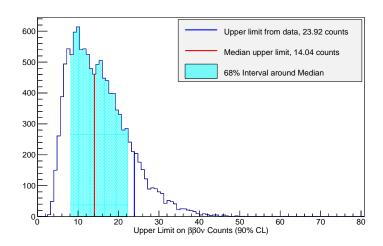

The Anscombe transformation (and generalizations) are designed to transform Poisson noise into Gaussian noise. However, for this purpose "noise" is defined to mean noise uncorrelated with pulse. We, on the other hand, are looking to understand noise which is correlated with the pulse, and then minimize its effect.

So, the Anscombe transformation doesn't really help us here.
